0.1 `negbin`: Negative Binomial Regression for Event Count Dependent Variables

Use the negative binomial regression if you have a count of events for each observation of your dependent variable. The negative binomial model is frequently used to estimate over-dispersed event count models.

Syntax

```
> z.out <- zelig(Y ~ X1 + X2, model = "negbin", data = mydata)
> x.out <- setx(z.out)
> s.out <- sim(z.out, x = x.out)
```

Additional Inputs

In addition to the standard inputs, `zelig()` takes the following additional options for negative binomial regression:

- `robust`: defaults to `FALSE`. If `TRUE` is selected, `zelig()` computes robust standard errors via the `sandwich` package (see Zeileis (2004)). The default type of robust standard error is heteroskedastic and autocorrelation consistent (HAC), and assumes that observations are ordered by time index.

  In addition, `robust` may be a list with the following options:

    - `method`: Choose from
        * `"vcovHAC"`: (default if `robust = TRUE`) HAC standard errors.
        * `"kernHAC"`: HAC standard errors using the weights given in Andrews (1991).
        * `"weave"`: HAC standard errors using the weights given in Lumley and Heagerty (1999).
    - `order.by`: defaults to `NULL` (the observations are chronologically ordered as in the original data). Optionally, you may specify a vector of weights (either as `order.by = z`, where `z` exists outside the data frame; or as `order.by = ~z`, where `z` is a variable in the data frame). The observations are chronologically ordered by the size of `z`.
    - `...`: additional options passed to the functions specified in `method`. See the `sandwich` library and Zeileis (2004) for more options.

Example

Load sample data:

```
> data(sanction)
```

Estimate the model:

```
> z.out <- zelig(num ~ target + coop, model = "negbin", data = sanction)

> summary(z.out)
```
Set values for the explanatory variables to their default mean values:

```
> x.out <- setx(z.out)
```

Simulate fitted values:

```
> s.out <- sim(z.out, x = x.out)

> summary(s.out)

> plot(s.out)
```

Predicted Values: Y|X

Expected Values: E(Y|X)

Model

Let Y_i be the number of independent events that occur during a fixed time period. This variable can take any non-negative integer value.

- The negative binomial distribution is derived by letting the mean of the Poisson distribution vary according to a fixed parameter ζ given by the Gamma distribution. The *stochastic component* is given by

$$
\begin{aligned}
Y_i \mid \zeta_i &\sim \text{Poisson}(\zeta_i \mu_i), \\
\zeta_i &\sim \frac{1}{\theta} \text{Gamma}(\theta).
\end{aligned}
$$

  The marginal distribution of Y_i is then the negative binomial with mean μ_i and variance $\mu_i + \mu_i^2/\theta$:

$$
\begin{aligned}
Y_i &\sim \text{NegBin}(\mu_i, \theta), \\
&= \frac{\Gamma(\theta + y_i)}{y! \, \Gamma(\theta)} \frac{\mu_i^{y_i} \, \theta^\theta}{(\mu_i + \theta)^{\theta + y_i}},
\end{aligned}
$$

  where θ is the systematic parameter of the Gamma distribution modeling ζ_i.

- The *systematic component* is given by

$$
\mu_i = \exp(x_i \beta)
$$

  where x_i is the vector of k explanatory variables and β is the vector of coefficients.

Quantities of Interest

- The expected values (`qi$ev`) are simulations of the mean of the stochastic component. Thus,

$$
E(Y) = \mu_i = \exp(x_i \beta),
$$

  given simulations of β.

- The predicted value (`qi$pr`) drawn from the distribution defined by the set of parameters (μ_i, θ).

- The first difference (`qi$fd`) is

$$
\text{FD} = E(Y|x_1) - E(Y \mid x)
$$

- In conditional prediction models, the average expected treatment effect (`att.ev`) for the treatment group is

$$
\frac{1}{\sum_{i=1}^{n} t_i} \sum_{i:t_i=1}^{n} \left\{ Y_i(t_i = 1) - E[Y_i(t_i = 0)] \right\},
$$

where t_i is a binary explanatory variable defining the treatment ($t_i = 1$) and control ($t_i = 0$) groups. Variation in the simulations are due to uncertainty in simulating $E[Y_i(t_i = 0)]$, the counterfactual expected value of Y_i for observations in the treatment group, under the assumption that everything stays the same except that the treatment indicator is switched to $t_i = 0$.

- In conditional prediction models, the average predicted treatment effect (att.pr) for the treatment group is

$$\frac{1}{\sum_{i=1}^{n} t_i} \sum_{i:t_i=1}^{n} \left\{ Y_i(t_i = 1) - \widehat{Y_i(t_i = 0)} \right\},$$

where t_i is a binary explanatory variable defining the treatment ($t_i = 1$) and control ($t_i = 0$) groups. Variation in the simulations are due to uncertainty in simulating $\widehat{Y_i(t_i = 0)}$, the counterfactual predicted value of Y_i for observations in the treatment group, under the assumption that everything stays the same except that the treatment indicator is switched to $t_i = 0$.

Output Values

The output of each Zelig command contains useful information which you may view. For example, if you run z.out <- zelig(y ~ x, model = "negbin", data), then you may examine the available information in z.out by using names(z.out), see the coefficients by using z.out$coefficients, and a default summary of information through summary(z.out). Other elements available through the $ operator are listed below.

- From the zelig() output object z.out, you may extract:

  - coefficients: parameter estimates for the explanatory variables.
  - theta: the maximum likelihood estimate for the stochastic parameter θ.
  - SE.theta: the standard error for theta.
  - residuals: the working residuals in the final iteration of the IWLS fit.
  - fitted.values: a vector of the fitted values for the systemic component λ.
  - linear.predictors: a vector of $x_i\beta$.
  - aic: Akaike's Information Criterion (minus twice the maximized log-likelihood plus twice the number of coefficients).
  - df.residual: the residual degrees of freedom.
  - df.null: the residual degrees of freedom for the null model.
  - zelig.data: the input data frame if save.data = TRUE.

- From summary(z.out), you may extract:

- **coefficients**: the parameter estimates with their associated standard errors, p-values, and t-statistics.
- **cov.scaled**: a $k \times k$ matrix of scaled covariances.
- **cov.unscaled**: a $k \times k$ matrix of unscaled covariances.

- From the **sim()** output object **s.out**, you may extract quantities of interest arranged as matrices indexed by simulation $\times$ **x**-observation (for more than one **x**-observation). Available quantities are:

  - **qi$ev**: the simulated expected values given the specified values of **x**.
  - **qi$pr**: the simulated predicted values drawn from the distribution defined by (μ_i, θ).
  - **qi$fd**: the simulated first differences in the simulated expected values given the specified values of **x** and **x1**.
  - **qi$att.ev**: the simulated average expected treatment effect for the treated from conditional prediction models.
  - **qi$att.pr**: the simulated average predicted treatment effect for the treated from conditional prediction models.
